Table 1 Evaluation results. To evaluate the DQI procedure suggested by the system, we measure DQ dimension, ML model performance, and K-S tests. The table at the top displays the assessment results for DQ issue ratios, while the table at the bottom shows the results based on the types of DQ issues. Note that the DQ issues(s) and DQI method(s) columns are labeled with the icon texts in the DQI view.

| Dataset | Rate | DQ issues(s) | DQI method(s) | Completeness | | Outlier | | Homogeneity | | Duplicate | | Correlation | | Relevance | | RMSE | | Model | K-S |

APPENDIX: STATISTICAL ANALYSIS

Table 1 shows the DQI procedures proposed by the system for the poisoning data and the evaluation results. Most data have higher DQ dimension scores due to DQI. In the table above, for the bike sharing dataset 30%, data completeness, outlier detection, correlation, and data relevance change from 86, 99, 57, and 71 to 100, 100, 57.14, and 78.57, respectively. In the table below, for the bike sharing dataset with missing values, data correlation and relevance detection change from 57 and 79 to 82 and 100, respectively. Additionally, most of the data enhances the ML model's performance due to DQI. In addition, since all data have a p-value of over than 0.05 in the K-S test, the system only proposes the appropriate DQI procedures. Note that since the data without the DQI procedure are the same before and after DQI, the p-value of the K-S test shows 1.

Some data also have lower DQ dimension scores. In the table above, for the forest fires dataset 10% and 30%, data correlation changes from 100 to 84.62. As mentioned in Section VI, this problem occurs because the system evaluates the new DQ based on the quality-improved data. Therefore, the score is not lowered. Also, depending on the data, the degree to which the ML model performance is enhanced due to DQI is different. For example, the forest fires dataset shows a significant decrease in RSME with DQIs, whereas the diabetes dataset shows little difference. Therefore, the user should analyze the effect of the ML model performance enhancement while improving the DQ.

The table placed at the top shows the results of the poisoned data to have different DQ issue ratios. The DQI procedure differs in the degree of improving the ML model performance according to the ratio of DQ issues. For example, the forest fires dataset 10% has a 53.1841 decrease in RSME, while 30% has a 75.3731 decrease. Also, for the bike sharing dataset and diabetes dataset 10%, none of the DQI procedures enhance the ML model performance compared to the original data. The reason is that since the lower the ratio of DQ issues, the less impact they have on the ML model performance, they are not addressed in the DQI procedure. Therefore, it is important to show high ML model performance even if DQ issues exist in the data. Notably, for the bike sharing dataset 25%, RMSE increases 332.4573 to 748.3867 after applying DQI. This issue is attributed to the batch application of DOI procedures for usability. Such cases highlight the necessity of customizing DQI pipelines based on context, as discussed in Section V.G.

The lower table summarizes the results of poisoned data, which exhibit various types of DQ issues. The system proposes different DQI procedures depending on the type of issue. For example, in the bike

sharing dataset with missing values, the DQ dimension scores for correlation and relevance improved after DQI. However, the corresponding procedure involved removing several features, which reduced the volume of data available for model training. This led to an increase in RMSE, indicating a potential trade-off between improving data quality and maintaining model performance. These findings underscore the need for customizing DQI procedures based on the specific task context, as discussed in Section V.G.

We evaluate whether the DQ dimension, K-S test, DQ issue ratio, and DQ issue types have statistically significant effects on the ML model performance from the ANOVA test. We randomly generate 100 DQI procedures per data for the ANOVA test and compute the DQ dimension, K-S test, DQ issue ratio, DQ issue type, and ML model performance. Afterward, we perform the ANOVA test by calculating the difference between the data before and after DQI for each independent variable. From the ANOVA test, all independent variables do not affect the ML model performance. As mentioned in Section II, this result is shown because the DQ issue that affects performance is different depending on the data and ML model. Therefore, the user needs to figure out the DQI methods and configure the order to perform them through the visual analytics system.
